Study on the temperature dependence of the bulk modulus of polyisoprene by molecular dynamics simulations

J. DIANI*, B. FAYOLLE and P. GILORMINI

Laboratoire d'Ingénierie des Matériaux, CNRS, ENSAM Paris, 151 bd de l'Hôpital, 75013 Paris, France.

The temperature dependence of the bulk modulus of polyisoprene has been studied using molecular dynamics simulations. Virtual polyisoprenes have been submitted to volume contractions above and below the glass transition. Bulk modulus has been observed to be linearly dependent on temperature both above and below the glass transition respectively, and it dropped by a factor of about 2 while temperatures was risen above the glass transition. By monitoring the energy changes during volume contractions, it was observed that the bulk modulus arises mainly from the Van der Waals interactions. Nevertheless, the entropy contribution to the bulk modulus becomes significant above the glass transition. At a first order, the entropy part of the bulk modulus can be considered as independent on the temperature.

Keywords: Molecular dynamics simulations; Polyisoprene; Bulk modulus; Glass transition; Compressibility.

1. Introduction

The small-strain elastic mechanical behaviour of isotropic materials is fully characterized by two parameters. One can choose for instance, the Young's modulus and the bulk modulus. Dealing with amorphous polymers, a specific dependence of these two parameters vs. temperature is observed. The Young's modulus is known to drop by one to three orders of magnitude while temperature rises above the glass transition temperature [1]. The bulk modulus is known to decrease by a factor of only 2 or 3 while temperature rises above the glass transition temperature [2]. The temperature dependence of the Young's modulus has been explained well in the literature [3]: above the glass transition, molecular mobility increases and enables entropic elasticity. However, the moderate drop of the bulk modulus is still not fully understood and the question of a possible entropy contribution to the bulk deformation is still open [4]. Tabor's [5] theoretical study of bulk modulus of rubber suggests that it arises from the Van der Waals interactions and that it is not related to the tensile modulus. Also, Theodorou and Suter's atomistic modelling [6] shows that entropy contributions to the elastic response to deformation can be

Email: julie.diani@paris.ensam.fr

neglected in polymer glasses. Conversely, Matheson's [4,7] reading of various experimental data of the literature seems to indicate that the entropy contribution cannot be generally neglected when considering the compressibility of polymeric glasses and rubbers. In this paper, we propose to address the question of the physical source of the bulk modulus of rubber (polyisoprene cis1-4) using molecular dynamics simulations.

Recently, the access to reliable affordable computers has contributed to the development of molecular dynamics simulations, and fully atomistic studies providing physical understandings on the mechanical behaviour of polymers are now possible. A number of studies have shown the ability of molecular dynamics to successfully reproduce the glass transition for amorphous polymers [8-11]. It is then reasonable to consider MD simulations to provide physical insight into the bulk modulus. This requires applying hydrostatic loadings, which are favourable for easy and fast MD simulations [12]. In such loadings, the number of degrees of freedom is reduced in comparison to uniaxial tension or shear. Using Materials Studio software [13], we built several virtual polyisoprenes and we applied hydrostatic compressions to the materials at various temperatures. During the simulations, the cell volume, pressure, and temperature were monitored, as well as the bonded, nonbond and kinetic energies. These data were used in a classical thermodynamics analysis to assess the physical source of the bulk modulus below and above the glass transition temperature.

2. General theory

We limit ourselves to hydrostatic loadings, which can result from an applied hydrostatic pressure p or from a volume contraction. The first law of thermodynamics relates a small change in internal energy U to small changes in entropy S and volume V , during quasi-static processes:

$$dU = TdS - pdV. \quad (1)$$

Considering the volume temperature T as two independent variables, Equation (1) leads to:

$$\left. \frac{\partial U}{\partial T} \right|_V = T \left. \frac{\partial S}{\partial T} \right|_V \quad \text{and} \quad \left. \frac{\partial U}{\partial V} \right|_T = -p + T \left. \frac{\partial S}{\partial V} \right|_T. \quad (2)$$

The isothermal bulk modulus is defined as:

$$B(T, V) = -V \left(\frac{\partial p}{\partial V} \right)_T, \quad (3)$$

and, by substituting Equation (2) in Equation (3) one gets

$$B(T, V) = V \left. \frac{\partial^2 U}{\partial V^2} \right|_T - VT \left. \frac{\partial^2 S}{\partial V^2} \right|_T, \quad (4)$$

which allows to define the internal energy contribution and the entropy contribution to the bulk modulus as:

$$B^U(T, V) = V \left. \frac{\partial^2 U}{\partial V^2} \right|_T \quad \text{and} \quad B^S(T, V) = -VT \left. \frac{\partial^2 S}{\partial V^2} \right|_T \quad (5)$$

In small strain elasticity, the bulk modulus refers to moderate volume contractions and is defined as

$B(T, V_0(T)) = B_0(T)$, where $V_0(T)$ corresponds to the volume of the material at temperature T and at atmospheric pressure. For various temperatures, we applied moderate volume contractions and used Equation (3) to obtain the bulk modulus as a function of temperature. During MD simulations, the internal energy of the system is computed as the sum of the bonded energy, the nonbond energy and the kinetic energy:

$$U = E_B + E_{NB} + K_c \quad (6)$$

The nonbond energy consists of the Van der Waals energy, the electrostatic energy and the hydrogen bond terms, while the bonded energy accounts for the valence interactions, such as bond stretching, dihedral angle torsion, valence angle bending, inversion.... The force-field used in Material Studio is COMPASS [14], which is an ab-initio-based force-field that has been validated on isolated molecules [15,16]. In COMPASS, the Van der Waals interactions are defined by a 9-6 Lennard-Jones potential. Having access to the variation of the internal energy U as a function of V , we can assess the internal energy contribution $B^U(T, V_0(T))$ through Equation (5) and, finally, the entropy contributions to $B_0(T)$ is deduced.

3. Molecular dynamics simulations

3.1. Procedure

Fully atomistic simulations were performed on periodic systems of cis-polyisoprene. The virtual materials were built using an amorphous cell generator provided in Materials Studio, with periodic boundary conditions. Each parent cell contains 5 chains of 300 monomers. The cubic parent cells were built at a high temperature (above the expected glass transition) of 400 K to ensure a better stability. Each system was then submitted to consecutive, energy minimization, 1 ns-NVT MD simulation (number of atoms, volume and temperature remain constant in a NVT ensemble), and 1 ns-NPT MD simulations (number of atoms, pressure and temperature remain constant in a NPT ensemble). This provided reasonably stable amorphous structures at atmospheric pressure and 400 K. The structures were then cooled down to 100 K with a series of 25 K to 50 K jumps with intermediate NPT MD steps running for 500 ps with a time step of 1 fs. The duration of the simulations is constrained by the relatively high number of atoms (19 510) and by the fact that we use fully atomistic simulations (and not coarse grain simulations). Nevertheless, to ensure that 500 ps were long-enough duration, we monitored the cell specific volume during 1 ns for NPTs at a low and a high temperature. As shown in Figure 1, the volume has converged before 500 ps.

Six cells were used to calculate the glass transition of the virtual materials. From these six cells, two were submitted to volume contractions in order to study the Bulk modulus temperature dependence. For each temperature, both cells were submitted to moderate 1.5% and 3%-volume contractions in order to calculate $B_0(T)$ according to Equation (3). Cell 1 simulations were run using Berendsen [17] barostat and thermostat, while cell 2 simulations used the Andersen [18] barostat and thermostat. Both methods provided similar results.

In addition, larger volume contractions were applied to both cells in order to better analyze the energy variations.

3.2. Results

During 1 bar-isobaric cooling, we observe a linear decrease of the specific volume at both high and low temperatures with decreasing temperature. The logarithm of the specific volume of the cells (volume per unit mass) is plotted vs. the temperature in Figure 2, so that the slope gives the coefficient of volumic thermal expansion directly. The change in the thermal contraction defines a clean glass transition at $T_g \sim 250$ K, which is 50 K above experimental values reported in the literature (~ 203 K at 10 K/min) [19] but is in good accordance with former MD studies on cis-polyisoprene [11]. From Figure 2, the expansion coefficients above and below T_g can be evaluated as $\alpha_r = 5.15 \times 10^{-4} \text{ K}^{-1}$ and $\alpha_g = 2.97 \times 10^{-4} \text{ K}^{-1}$, respectively, in qualitatively good agreement with values reported in the literature [19], $\alpha_r = 6.16 \times 10^{-4} \text{ K}^{-1}$ and $\alpha_g = 2.07 \times 10^{-4} \text{ K}^{-1}$.

In order to assess the material compressibility, we first submitted cell 1 to an increasing volume contraction at 350 K. The resulting pressure is plotted in Figure 3 as a function of the logarithm of the specific volume of the cell. We note that the material stiffens as the volume decreases, which indicates that compressibility decreases with volume contraction. This result is consistent with rubber behaviour reported in the literature [20]. As previously mentioned, the bulk modulus is related to the material response for small volume contractions and is defined by the linear approximation of p vs. $\ln(V(T))$ according to Equation (3). Figure 3 illustrates how $B_0(350)$ is estimated to be 1460 MPa. For each temperature, the bulk modulus $B_0(T)$ is calculated using three states: atmospheric pressure and resulting volume $V_0(T)$, 1.5%-volume contraction, 3%-volume contraction. In Figure 4, the values of the bulk modulus are plotted vs. temperature for cells 1 and 2, and a linear relation can be considered both above and below the glass transition temperature. Below T_g , a rise in temperature produces a decrease of the bulk modulus twice as important as above T_g . We obtained a value of 2100 MPa for $B_0(300)$, which is in good agreement with the value of 2020 MPa reported in the literature [21]. Around the glass transition, $B_0(T)$ varies more significantly, and the ratio of the bulk modulus at 200 K (50 K below T_g) over the bulk modulus at 300 K (50 K above T_g) is close to 2. A change of such a magnitude through the glass transition is consistent with the experimental behaviour reported in amorphous polymers [2]. Therefore, the bulk modulus temperature dependence presented by our virtual materials is representative of the behaviour of a real polyisoprene. Consequently, in an attempt to provide some physical understandings of the material compressibility, the system energy changes have been monitored during volume contractions at fixed temperature and during temperature changes at fixed volume.

Cell 1 was submitted to several volume contractions at three fixed temperatures 350 K, 250 K and 150 K and stabilized by NVT simulations. During these simulations, we have collected the changes of the three component

of the internal energy (Equation (6)): the bonded energy, the nonbonded energy and the kinetic energy. Considering the latter, only a change of temperature affects K_c since by definition $K_c = 3Nk_B T / 2$, where k_B is the Boltzmann's constant, N is the number of atoms and T the temperature. Consequently, the kinetic energy remains constant during volume contractions at constant temperature. In Figure 5, the bonded energy is plotted vs. the cell specific volume for the three temperatures. In order to provide a simple read of the data in a single Figure for all temperatures, the bonded energy was normalized for each temperature by its maximum value, which was obtained for the highest contraction (or equivalently smallest volume). At 350 K, above T_g , the bonded energy remains constant through volume contractions. At 150 K, the bonded energy fluctuates around a plateau value for moderate contractions, including those applied to determine the bulk modulus. Then, for severe volume contractions, the bonded energy increases drastically. At 250 K, the same trend for the bonded energy as at 150 K is recognized, though it is subtler: the bonded energy does not vary for moderate volume contractions and it increases evidently for high contractions. Therefore, it can be concluded that, at both high and low temperatures, the bonded energy does not vary significantly when volume contraction keeps within the range used to compute the bulk modulus.

As mentioned previously, three sources may contribute to the nonbonded energy: the Van der Waals interactions, the electrostatic forces and the hydrogen bonds. Since polyisoprene has no hydrogen bond and electrostatic forces are found constant under the applied loadings, the computed nonbond energy changes amount to Van der Waals energy changes only. The latter are shown in Figure 6 vs. the cell specific volume. For each temperature, the curve shape is reminiscent of a Lennard-Jones potential. The Van der Waals energy per unit mass varies with temperature, but Figure 7 shows that the three curves coincide reasonably if a suitable vertical translation is applied. This result allows the Van der Waals energy per unit mass to be written as:

$$E_{vdw}(T, V) = E_{vdw}(T_0, V) + \beta(T - T_0), \quad (7)$$

with $\beta = 356 \text{ J.kg}^{-1}.\text{K}^{-1}$ if T_0 is taken as 350 K. From Figures 5 and 6, we conclude that when the virtual polyisoprenes are submitted to moderate volume contractions (which are the contractions that define the bulk modulus), only the Van der Waals energy varies significantly among the various terms contributing to the internal energy. Cell 2 was submitted to volume contractions at 400 K, 350 K and 150 K and lead to similar results than those presented above; they will be used to strengthen the analysis in the next section. The data obtained from the volume contractions at constant temperature will be useful to determine $B^U(T, V_0(T))$ and, by subtracting to $B_0(T)$, to estimate the contribution of entropy to the bulk modulus.

4. Van der Waals contribution to the bulk modulus

Since the Van der Waals energy changes, in the range of volume contractions considered to compute the bulk modulus, leads the internal energy changes, Equation (5) gives

$$B_0^U(T) = B^U(T, V_0(T)) = V_0(T) \left. \frac{\partial^2 U}{\partial V^2} \right|_T \approx V_0(T) \left. \frac{\partial^2 E_{vdw}}{\partial V^2} \right|_T. \quad (8)$$

Figure 7 suggests that a simple equation should be able to approach the Van der Waals energy per unit mass. Actually, the 9-6 Lennard-Jones potential used at the local scale to define the Van der Waals interactions suggests trying to apply the same function to the overall Van der Waals energy of the cell, and the Equation (7) would write:

$$E_{vdw}(T, V) = \frac{a}{V^3} - \frac{c}{V^2} + \beta(T - T_0). \quad (9)$$

As shown Figure 8, Equation (9) does fit the Van der Waals energies for cells 1 and 2 relatively well when $a=1.90 \cdot 10^{-3} \text{ J.m}^9 \cdot \text{kg}^{-4}$, $c=2.81 \text{ J.m}^6 \cdot \text{kg}^{-3}$ are used for cell 1 and $a=2.0 \cdot 10^{-3} \text{ J.m}^9 \cdot \text{kg}^{-4}$, $c=2.96 \text{ J.m}^6 \cdot \text{kg}^{-3}$ for cell 2.

By substitution of Equation (9) in Equation (8), the following simple form is obtained for $B_0^U(T)$:

$$B_0^U(T) = \frac{12a}{V_0^4(T)} - \frac{6c}{V_0^3(T)} \quad (10)$$

For any temperature T , $V_0(T)$ can be evaluated from the two-part linear fit shown in Figure 2, and thus $B_0^U(T)$ can be computed from Equation (10) and compared to $B_0(T)$. This comparison is presented in Figure 9 for cells 1 and 2. For temperatures below the glass transition, it can be observed that the bulk modulus $B_0(T)$ is close to $B_0^U(T)$, though the values of $B_0(T)$ are slightly underestimated in cell 2. Since the latter is computed from the Van der Waals energy only, which dominates the internal energy, no significant entropy contribution is noticed in the glassy state. In contrast, $B_0^U(T)$ overestimates the bulk modulus above the glass transition. This overestimation indicates that entropy does contribute to the bulk modulus above the glass transition. We note that the entropy affects the bulk modulus by reducing it (in the sense that $B_0(T)$ is lower than $B_0^U(T)$). In Figure 9, plotting the parallel to the values of $B_0^U(T)$ passing through the values of $B_0(T)$ shows that the entropy contribution $B_0^S(T)$ to $B_0(T)$ may be considered as independent of temperature to the first order, with an average value of -400 MPa for cell 1 and -300 MPa for cell 2.

5. Conclusion

Molecular dynamics simulations were performed on virtual polyisoprenes in order to investigate the physical source of the bulk modulus above and below the glass transition. The materials were submitted to moderate volume contractions at fixed temperature through NVT simulations, in order to estimate the bulk modulus dependence on temperature. The bulk modulus values thus obtained were shown to be in qualitative and quantitative good agreements with data reported in the literature. In particular, the bulk modulus showed a drop by a factor of about 2 at the glass transition. Investigating the internal energy change during volume contractions at constant temperature, we observed that for moderate contractions, sufficient to estimate the bulk modulus, the internal energy change arises from the Van der Waals energy only. Hence, by approaching the overall Van der Waals energy by a 9-6 Lennard-Jones potential, and by applying a classical thermodynamic analysis, the internal

energy contribution to the bulk modulus was estimated below and above the glass transition. This contribution was shown to reproduce fairly well the bulk modulus below the glass transition but to overestimate it above. In the latter temperature range, entropy changes lessen the bulk modulus by an amount that can be considered as temperature independent to first order.
